Fronto–Temporal Disconnectivity in Schizotypal Personality Disorder: A Diffusion Tensor Imaging Study

Motoaki Nakamura, Robert W. McCarley, Marek Kubicki, Chandlee C. Dickey, Margaret A. Niznikiewicz, Martina M. Voglmaier, Larry J. Seidman, Stephan E. Maier, Carl-Fredrik Westin, Ron Kikinis, and Martha E. Shenton

Background: 
Using diffusion tensor imaging (DTI), we previously reported abnormalities in two critical white matter tracts in schizophrenia, the uncinate fasciculus (UF) and the cingulum bundle (CB), both related to fronto–temporal connectivity. Here, we investigate these two bundles in unmedicated subjects with schizotypal personality disorder (SPD).

Methods: 
Fifteen male SPD subjects and 15 male control subjects were scanned with line-scan DTI. Fractional anisotropy (FA) and mean diffusivity ($D_m$) were used to quantify water diffusion, and cross-sectional area was defined with a directional threshold method. Exploratory correlation analyses were evaluated with Spearman’s rho, followed by post hoc hierarchical regression analyses.

Results: 
We found bilaterally reduced FA in the UF of SPD subjects. For CB, there was no significant group difference for FA or $D_m$ measures. Additionally, in SPD, reduced FA in the right UF was correlated with clinical symptoms, including ideas of reference, suspiciousness, restricted affect, and social anxiety. In contrast, left UF area was correlated with measures of cognitive function, including general intelligence, verbal and visual memory, and executive performance.

Conclusions: 
These findings in SPD suggest altered fronto–temporal connectivity through the UF, similar to findings in schizophrenia, and intact neocortical–limbic connectivity through the CB, in marked contrast with what has been reported in schizophrenia.

Key Words: 
Diffusion tensor imaging, schizotypal personality disorder, uncinate fasciculus, cingulum bundle, fronto–temporal connectivity, fractional anisotropy

Schizotypal personality disorder (SPD) and schizophrenia share a common genetic diathesis, and many of the same phenomenological features, including cognitive distortion, social deficits, and restricted affectivity. They differ, however, in that both do not evince psychotic symptoms (see reviews in Dickey et al 1999, 2002b; Downhill et al 2001; Hirayasu et al 2000a, 2000b). These findings suggest a common endophenotype in these brain regions, which further suggest a predisposition toward neurodevelopmental aberrations.

With respect to frontal lobe regions, there are reports of volume reduction in schizophrenia (see review in Shenton et al 2001), however, with the exception of one study showing a lack of normal right > left asymmetry in the anterior cingulate gyrus of female SPD subjects (Takahashi et al 2002), compatible with findings in schizophrenia (Goldstein et al 1999), frontal lobe abnormalities have not been reported in SPD (Buchsbaum et al 2002).

Also of note, fronto–temporal connectivity abnormalities in schizophrenia have long been of interest (Akbarian et al 1996; Benes 2000; Deakin and Simpson 1997; Friston and Frith 1995; Kraepelin 1919/1971; McGuire and Frith 1996; Meyer-Lindenberg et al 2001; Weinberger et al 1992; Wermicke 1906), though their role in SPD has not been thoroughly investigated. With the advent of diffusion tensor imaging (DTI), however, neural connectivity can be assessed, because subtle white matter abnormalities can be evaluated, including organization and coherence (Basser 1995; Basser et al 1994; see also Kubicki et al 2002b for review).

Indeed, impaired white matter integrity within prefrontal (Buchsbaum et al 1998) and temporal lobes (Ardekani et al 2003), as well as abnormalities within the fiber bundles connecting these regions, including the uncinate fasciculus (UF) (Burns et al 2003; Kubicki et al 2002a), cingulum bundle (CB) (Kubicki et al 2003; Sun et al 2003; Wang et al 2004), and arcuate fasciculus (Burns et al 2003), are the most frequent findings in recent DTI studies in schizophrenia. In addition, diffusion abnormalities in the genu of the corpus callosum (Agartz et al 2001; Ardekani et al 2003; Foong et al 2000b, 2002), internal capsule (Buchsbaum et al 1998), and in whole white matter (Lim et al 1999; Minami et al 2003) have been reported in schizophrenia.
In the present study, we evaluated white matter integrity of the UF and CB, using anisotropy (fractional anisotropy; \(FA\)) and diffusivity (mean diffusivity; \(D_m\)) of water molecule movement (Papadakis et al 1999) in SPD and control subjects. We also evaluated the cross-sectional area, using a directional threshold method (Kubicki et al 2002a, 2003). We selected these two fiber tracts because our group has shown them to be abnormal in schizophrenia (Kubicki et al 2002a, 2003). We also note that the UF interconnects with the anterior temporal and inferior frontal cortices (Ebeling and von Crumon 1992; Kier et al 2004; Klingler and Gloor 1960; Kondo et al 2003; Petrides and Pandya 1988; Ungerleider et al 1989) and that the CB connects the cingulate gyrus with prefrontal, temporal, and parietal areas (Goldman-Rakic 1988; Vogt et al 1979), regions likely important in schizophrenia and by extension SPD. We hypothesize that UF and CB white matter integrity might also be altered in an unmeculated SPD population. To our knowledge, this is the first study applying DTI techniques to SPD.

Methods and Materials

Subjects

Subjects were 15 neuroleptic-naive male SPD subjects (SPDs) and 15 male normal control subjects (NCs), all right-handed. Demographic data are summarized in Table 1. The SPDs and NCs were recruited from advertisements. Inclusion criteria were 1) age 18–55 years; 2) English as the primary language; 3) no history of neurological disorders; 4) no history of substance dependence ever or abuse in the last year; 5) no lifetime use of opioids, sedatives or other hypnotics, stimulants or anxiolytics, or other medications that might affect magnetic resonance imaging (MRI). For SPDs only, clinical symptoms of diagnosis and to test interrater reliability for SPD diagnosis, which was high (\(κ = .89, n = 25\)) (Dickey et al 1999). This study was approved by the institutional review boards of the VA Boston Healthcare System and Harvard Medical School. Written informed consent was obtained from all subjects before study participation.

Clinical and Neuropsychological Measures

Handedness was evaluated with the Edinburgh inventory (Oldfield 1971). Socioeconomic status (SES) of SPDs and NCs and their parents was evaluated with the Hollingshead two-factor index (Hollingshead 1965). For SPDs only, clinical symptoms were measured with the Structured Interview for Schizotypy (SIS; Kendler et al 1989, 1995), Scale for the Assessment of Positive Symptoms (SAPS; Andreasen 1984), and Scale for the Assessment of Negative Symptoms (SANS; Andreasen 1981). For self-report clinical measures, we used the Schizotypal Personality Questionnaire (SPQ; Raine 1991), the Beck Depression Inventory (BDI; Beck 1978), and the State-Trait Anxiety Inventory (STAI; Spielberger 1983).

As part of a comprehensive neuropsychological battery, subjects from both groups were evaluated with the Wechsler Adult Intelligence Scale (WAIS-III; Wechsler 1997a); the Boston Naming Test (Kaplan et al 1983), a test related to language function; the California Verbal Learning Test (CVLT) (semantic cluster score and the semantic cluster ratio; Delis et al 1987), a word-list learning test that requires semantic clustering for more efficient performance; the Wechsler memory scale (WMS-III; Wechsler 1997b), including immediate and delayed measures of verbal and visual memory; the Rey-Osterrieth complex figure test (Lezak 1995), a visual memory task; the Wisconsin Card Sorting Test (WCST; Heaton 1981), a measure requiring concept formation, abstraction, and mental flexibility; and the Trail Making Test (Reitan 1958), a measure of visuomotor processing speed.

Data for subjects recruited before the introduction of some of the tests, most notably the WMS-III, were not available. Moreover, a few subjects elected not to participate in some measures.

MRI Acquisition and Data Processing

Subjects were scanned with line scan diffusion tensor imaging (LSDI) (Gudbjartsson et al 1996; Maier et al 1998), a DTI technique based on sequential acquisition of parallel columns lying in the image plane. This information is described elsewhere (Kubicki et al 2004). Briefly, MR scans were performed with a quadrature head coil on a 1.5-Tesla GE Echospeed system (General Electric Medical Systems, Milwaukie, Wisconsin), which permits maximum gradient amplitudes of 40 mT/m. We began with three orthogonal T1-weighted images used as localizers (sagittal, axial oblique aligned to the anterior commissure–posterior commissure [AC–PC] line, and another sagittal oblique aligned to the interhemispheric fissure). From the last sagittal oblique T1-weighted image, the LSDI sequence in coronal orientation was then aligned perpendicular to the AC–PC line. For each slice, six images with high \((1000 \text{ sec/mm}^2)\) diffusion weighting along six noncollinear and noncoplanar directions and two images with low \((5 \text{ sec/mm}^2)\) diffusion weighting were collected. For low diffusion weighting, we collected only two images because the diffusion-related signal changes are minimal. The following scan parameters were used: field of view \(220 \times 165\) mm; \(128 \times 96\) scan matrix \((256 \times 192\) image matrix\); slice thickness \(= 4\) mm; interslice distance \(= 1\) mm; receiver band-width \(= \pm 4\) kHz; echo time \(= 64\) msec; effective repetition time =

2592 msec; scan time = 60 sec per slice section. We acquired 31–35 coronal slices covering the entire brain, depending on brain size. Total scan time was 31–35 min. After reconstruction, diffusion-weighted images were transferred to a SUN worksta-
tion (Sun Microsystems, Santa Clara, California), on which eig-
envalues ($\lambda_1$, $\lambda_2$, and $\lambda_3$), eigenvectors, $D_m$, and FA were
calculated. Fractional anisotropy, a measure of the fraction of the
magnitude of the tensor that can be ascribed to the anisotropic
diffusion, and $D_m$, the average of three eigenvalues of the tensor,
were calculated with the following formula (Papadakis et al
1999):

$$FA = \sqrt{\frac{\left(\lambda_1 - \lambda_2\right)^2 + \left(\lambda_1 - \lambda_3\right)^2 + \left(\lambda_2 - \lambda_3\right)^2}{2\left(\lambda_1^2 + \lambda_2^2 + \lambda_3^2\right)}},$$

$$D_m = \frac{\lambda_1 + \lambda_2 + \lambda_3}{3} \text{ (} \mu\text{m}^2/\text{msec)}$$

**Definition of Bundles**

The UF and CB regions of interest (ROIs) were automatically
defined by thresholding the out-of-plane principal diffusion
component ($\lambda_{1z}$), which was calculated with this formula:

$$\lambda_{1z} = \lambda_1 \times e_{1z} \text{ (} \mu\text{m}^2/\text{msec)}$$

where $\lambda_1$ is the largest eigenvalue, and $e_{1z}$ is the out-of-plane
component of the eigenvector associated with the largest eigen-
value ($\lambda_1$) (Figure 1). We used 1.1 $\mu\text{m}^2/\text{msec}$ as the common
threshold for both bundles for all subjects. This directional
threshold was a little higher than 1.0 $\mu\text{m}^2/\text{msec}$ of our previous
study (Kubicki et al 2002a, 2003).

For UF, we selected one coronal slice, perpendicular to the
AC-PC line, which intersects UF in the anterior temporal stem.
This is the densest portion of the UF fiber tract, but sometimes
there were two possible slices in which the UF seemed to be
distributed densely. In that case, we compared the mean $\lambda_{1z}$
magnitude above the threshold of 1.1 $\mu\text{m}^2/\text{msec}$ and then
selected the one slice that showed the larger $\lambda_{1z}$ value to focus
on the out-of-plane component of the UF. Subsequent manual
exclusion of uncertain voxels from the ROI was not needed
because we used a higher threshold.

For the CB ROI, we excluded ROI outside of the anterior
and posterior boundaries defined by the genu and splenium of
corpus callosum and included ROI inside these regions to
focus on the out-of-plane component of CB. That is, the most
anterior coronal slice in which the corpus callosum was
separately seen above and below was the first slice of CB, and
the most posterior coronal slice in which the corpus callosum
was separately seen above and below was the last slice of CB.
There were 9–12 coronal slices that met this criterion for CB
slice selection.

For UF DTI measures, FA and $D_m$ were averaged within an
ROI, and cross-sectional area of the ROI was calculated accord-
ing to the number of voxels within the ROI, for subsequent group
comparison. For CB DTI measures, the average values of FA, $D_m$,
and cross-sectional area within an ROI were summed over all CB

![Figure 1. Definition of fiber bundles. (Left panel) Three-directional principal diffusion components having the largest eigenvalues ($\lambda_1$) on the coronal plane of the fractional anisotropy (FA) map. We used the out-of-plane principal diffusion component of maximum diffusivity ($\lambda_{1z}$) to define both bundles of uncinate fasciculus (UF) and cingulum bundle (CB) semi-automatically. The common threshold was 1.1 $\mu\text{m}^2/\text{msec}$ for both bundles in all cases for both groups. (Right panel) Uncinate fasciculus (red) and CB (blue) on FA maps of a normal control subject (NC) and a schizotypal personality disorder subject (SPD). Note the smaller area and decreased intensity in UF of the SPD subject (indicated by red arrows). R, right; L, left.](image-url)
slices, and then these three DTI measures were averaged by the total number of serial CB slices for subsequent group comparison.

**Statistical Analysis**

Student t tests were performed to assess group differences in age, SES, parental SES, years of education, and total intelligence quotient (IQ). For diffusion measures, repeated-measures analysis of variance (ANOVA) was applied to mean FA, $D_m$, and cross-sectional areas for both UF and CB. We used left and right hemispheres as the within-subject factor and diagnostic group as the between-subjects factor. To evaluate the likely importance of these findings, we also computed Cohen’s effect size (Cohen 1988).

Clinical/cognitive correlations with DTI measures (i.e., mean FA, $D_m$, and cross-sectional area of UF and CB) were evaluated with Spearman’s rho ($\rho$). Correlations were evaluated on an exploratory basis, with $p < .05$ as the cut-off for reporting statistical significance, rather than by using a correction for multiple correlations. We selected Spearman $\rho$ correlations because we used small sample sizes (Siegel and Castellan 1988) and because some measures were not normally distributed, as demonstrated by a significant Shapiro-Wilk statistic ($p < .05$ for both groups; BDI, WCST [percent perseverative errors and number of trials to complete first category]; for SPDs: left UF area, visual reproduction [immediate recall] of WMS-III, Rey-Osterrieth complex figure test [delayed recall]; for NCs: right CB area, estimated total IQ of WAIS-III, total correct score of Boston naming test, and visual reproduction [delayed recall] of WMS-III). Finally, following the Nestor et al. (2004) study of schizophrenia and following our correlational findings between FA measures and clinical/cognitive measures, we next used hierarchical regression to explore further the pattern of correlations. The Student t test was used to evaluate group difference between SPN and NC groups in cognitive measurements.

**Results**

**Demographic Data**

There were no significant differences between groups in terms of age, SES, parental SES, length of education, or total IQ (see Table 1).

DTI Measures of Uncinate Fasciculus

Descriptive statistics of DTI measures and results of repeated-measures ANOVA are summarized in Table 2. Repeated-measures ANOVA revealed that SPDs, compared with NCs, showed lower mean FA [F(1,28) = 7.50, $p = .01$] and higher $D_m$ [F(1,28) = 1.02, $p = .32$] of left UF. Subjects with SPD, compared with NCs, had higher $D_m$ [F(1,28) = 5.53, $p = .07$], with a trend-level difference bilaterally for UF. For cross-sectional area of UF, there was no significant group difference [F(1,28) = .17, $p = .68$]. The effect sizes of Cohen’s d were medium to large for mean FA (left UF = .55, right UF = 1.10) and $D_m$ (left UF = .57, right UF = .63) but small for mean area (left UF = .16, right UF = .10).

**DTI Measures of CB**

For CB, there were no significant group differences in mean FA [F(1,28) = .11, $p = .75$] (see Figure 2), $D_m$ [F(1,28) = .31, $p = .59$], or in cross-sectional area [F(1,28) = .41, $p = .53$]. There were, however, significant left > right asymmetries for CB in mean FA [F(1,28) = 39.17, $p < .001$], $D_m$ [F(1,28) = 7.08, $p = .01$], and cross-sectional area [F(1,28) = 12.17, $p = .002$], compatible with previous findings in schizophrenia (Kubicki et al. 2003; Wang et al. 2004). For number of slices selected for CB, there was no significant difference [t(28) = .21, $p = .84$] between SPDs (10.5 ± .92 slices) and NCs (10.5 ± .83 slices). All DTI measures of CB showed small effect sizes of Cohen’s d (e.g., effect size of left CB FA = .03), suggesting that it would be difficult to obtain sufficient power to detect group differences even if the sample size was greatly increased.

**DTI Correlations with Clinical and Cognitive Measures**

**Correlations with UF.** In the correlation analyses, summarized in Table 3, reduced right UF FA for SPDs was negatively correlated with the SIS for “ideas of reference” ($\rho = -.62$, $p = .02$) and “suspiciousness” ($\rho = -.67$, $p = .01$) and on the SPQ for interpersonal score ($\rho = -.62$, $p = .03$), which consists of four subscales of excessive social anxiety, no close friends, constrained affect, and suspiciousness (see Figure 3). Also of note, reduced right UF FA was negatively correlated with total score on the BDI ($\rho = -.73$, $p = .002$) (see Figure 3) and trait anxiety from the STAI ($\rho = -.68$, $p = .02$) for SPD subjects only.

groups are shown. The minimum value of FA is 0, indicating isotropic water (CB) of schizotypal personality disorder (SPD) and normal control (NC).

Figure 2.

In contrast to right UF FA, which demonstrated significant correlations with clinical symptoms, the left UF area was correlated with general intelligence, language, verbal and visual memory, and executive functions in SPDs, with the exception of WAIS-III vocabulary aged scaled score (p = .41, p = .44). Moreover, for all correlations with left UF area, only WAIS-III vocabulary aged scaled score showed the same variance. Likewise, the right UF area was negatively correlated with SPDs' age (left: p = .73, p = .003; right: p = .58, p = .03) and cued recall (left: p = .89, p = .001; right: p = .65, p = .01), and positively correlated with WMS-III memory for faces delayed recall (left: p = .78, p = .005; right: p = .75, p = .008). Left CB area was correlated negatively with total score of SANS (p = .58, p = .03) and positively with block design aged scaled score in WAIS-III (p = .60, p = .03) within SPDs. The same or similar correlations were not observed in NCs.

Post Hoc Hierarchical Regression Analyses

As noted above, left and right UF correlated with different functional variables. For SPDs, left UF area correlated with lower scores on tests of verbal memory and language, whereas reduced right UF FA correlated with symptom/personality ratings. These univariate correlations thus revealed evidence of dissociation between verbal abilities and left UF on one hand and clinical symptoms and right UF on the other. To control for inflation of type I error in calculating multiple univariate correlations, we explored and tested this structure–function dissociation with hierarchical regression. We first regressed left UF and right UF over verbal memory, because our prior studies of patients with schizophrenia showed that left UF uniquely accounted for performance on verbal memory (see Nestor et al 2004). Specifically, we entered both brain regions (left UF, right UF) as predictors in a hierarchical regression, first with the CVLT as the dependent variable and then with SPQ (interpersonal score) as the dependent variable.

Findings showed that for the CVLT, left UF area revealed a significant R² change of .51 [F(1,12) = 12.55, p < .01], in contrast to the nonsignificant R² change of .05 [F(1,11) = .65, p = .44] accounted for by the right UF area. Left UF area and CVLT total words learned aged scaled score revealed a partial correlation value of .73 and a semipartial correlation value of .72, as compared with values of .23 and .16 for right UF area and CVLT total words learned aged scaled score. These values indicate that left UF area uniquely accounted for 53.3% and 51.8% of the variance in CVLT total words learned aged scaled score, whereas the right UF area accounted for 5.3% and 2.6% of the same variance. Further analyses demonstrated that only left UF area [β = .79, t(11) = 3.51, p < .01] contributed significantly to the CVLT score.

We then regressed right UF and left UF over symptoms, selecting overall level of SPQ traits as the dependent variable most likely to describe the clinical phenomenology of our sample. For SPQ (interpersonal score), right UF FA produced a significant R² change of .36 [F(1,11) = 6.22, p = .03], as compared with the nonsignificant R² change of .03 [F(1,10) = .41, p = .54] accounted for by the left UF FA. Right UF FA and SPQ (interpersonal score) revealed a partial correlation value of .60 and a semipartial correlation value of .59, as compared with values of .20 and .16 for left UF FA and SPQ (interpersonal score). These values indicate that the right UF FA uniquely accounted for 36.0% and 54.8% of variance in SPQ (interpersonal score), whereas left UF FA accounted for 4.0% and 2.6% of the same variance. Likewise, the right UF FA [β = −.59, t(10) = −2.38, p = .04] but not the left UF FA contributed significantly to SPQ (interpersonal score).

Discussion

Diffusion tensor imaging findings from the present study strongly suggest that fronto–temporal connectivity through the UF, one of the most prominent fiber bundles connecting the
frontal and temporal lobes, is altered in SPD, and that this alteration shows an interesting dissociation between the left UF area and verbal deficits on one hand and reduced right UF anisotropy and increased clinical symptoms on the other. Moreover, the observed DTI correlations with clinical and cognitive measures suggest that a disturbance in connectivity between different brain regions, rather than abnormalities within the separate regions themselves, might be responsible for some of the observed clinical symptoms and cognitive dysfunctions in SPD.

Compared with previous DTI findings on schizophrenia, findings of bilaterally abnormal UF integrity in male subjects with SPD are similar to findings reported in schizophrenia, although two previous DTI studies (Burns et al. 2003; Kubicki et al. 2002a) in schizophrenia showed reduced anisotropy in left UF; more specifically, reduced normal left > right asymmetries in UF anisotropy (Kubicki et al. 2002a) and a trend-level reduction in left UF anisotropy (Burns et al. 2003). In contrast, there were no significant differences in CB between SPDs and NCs, whereas we previously reported CB abnormalities in schizophrenia.

The fact that there is some overlap between findings in SPD and schizophrenia suggests that SPD might be a “forme fruste” or “milder” presentation of pathology among the schizophrenia spectrum disorders, rather than a categorical classification, such as in DSM-IV. Accordingly, the similarity in findings for UF anisotropy in SPD and schizophr-
nia suggests that UF integrity disruption might be along a continuum of dysfunction. This lack of UF cohesion in the schizophrenia spectrum is reminiscent of classic disconnection syndromes (Mesulam 1985), in that a lack of integration between two brain regions results in specific deficits. In schizophrenia and SPD, but unlike isolated lesions found in the classic disconnection syndromes, the deficits are more widespread and result in a larger range of abnormalities, as exemplified by the range of correlations described in this report.

One potential pathogenic explanation for this more widespread abnormality might come from postmortem data. On the
basis of histochemical studies of postmortem brains of schizophrenic subjects, Deakin and Simpson (1997) proposed that an abnormal amount of glutamatergic innervation from orbitofrontal cortex to anterior temporal cortex through UF might be an essential neurodevelopmental abnormality for schizophrenia. This glutamatergic excitotoxicity might result in reduced UF anisotropy in both schizophrenia and SPD populations.

In contrast, areas of dissimilarity between SPD and schizophrenia, such as observed for CB anisotropy, suggest that there might be certain protective factors operating in SPD that might contribute to more limited clinical symptoms compared with schizophrenia. More specifically, Siever and Davis (2004) speculate that there is a “greater frontal capacity in SPD than schizophrenia.” Because CB projects disproportionately to the frontal lobe, the finding of disrupted CB in schizophrenia, but not in SPD, supports Siever and Davis’ hypothesis that the prefrontal cortex in SPD acts to “buffer” other brain regions against the decimating effects of an abnormal temporal lobe (Siever and Davis 2004). Intact CB in SPD might therefore represent part of that prefrontal “buffer.”

Also noteworthy were the clinical correlations with DTI measures in SPDs, suggesting that altered temporal–frontal connectivity through the UF might play an important role in the phenomenology of SPD. Specifically, reduced FA in right UF was correlated with clinical symptoms, including ideas of reference (SIS), suspiciousness (SIS, SPQ), restricted affect (SPQ, BDI), and no close friends (SPQ). In contrast, cognitive correlations with DTI in SPDs showed that the left UF area was correlated with measures of general intelligence, verbal and visual memory, and executive functions. These latter correlations are consistent with previous neuropsychological findings in SPD, which have shown decrements in general intelligence (Mitropoulou et al 2002; Voglmaier et al 2000), in performance on the CVLT (Voglmaier et al 1997), and in visual reproduction on the WMS-III (Mitropoulou et al 2002), as well as poor performance on executive functions, such as the WCST and the Trail Making Test (Mitropoulou et al 2002; Trestman et al 1995), all of which provide further evidence that fronto–temporal disconnectivity through the left UF might play a crucial role in cognitive distortion in SPD. The Rey-Osterrieth Complex Figure test, however, demonstrated right-dominant correlations, possibly reflecting contributions of visual memory and visuo-spatial planning, which are required in this test.

Of interest to the present study, a recent DTI study of schizophrenia by Nestor et al (2004) reported reduced left UF FA in schizophrenic subjects compared with control subjects, which was correlated with lower declarative–episodic verbal memory, whereas reduced left CB cross-sectional area correlated with errors in executive functions related to performance monitoring. The association between verbal memory and left UF is similar to that reported here for SPD. Moreover, results from the hierarchical multiple regression analyses in the present study provide evidence of dissociation between disruptions of left UF and reduced verbal memory on the one hand and right UF and SPQ traits on the other.

Anatomically, UF interconnects with anterior temporal and inferior frontal regions. More specific links include connecting amygdala and uncus with subcallosal regions (Ebeling and von Cramon 1992; Kier et al 2004; Klingler and Gloor 1960). A human histochemical study has shown that UF also carries cholinergic fibers from the basal nucleus of Meynert, as a part of cholinergic pathway that supplies frontal, parietal, and temporal neocortices, and perisylvian division of frontoparietal operculum, insula, and superior temporal gyrus (Selden et al 1998). Also of note, UF is closely related to the ventral visual pathway (Ungerleider et al 1989), although dissection studies with monkeys reveal that UF dissection itself did not yield visual memory disturbances alone (Gaffan and Eccott 1995a, 1995b). Results from the present study, in light of these anatomical findings, suggest that UF-mediated neural circuits involving the amygdala might be attributed to emotional aspects of SPD pathophysiology. Altered cholinergic innervation through the UF with decreased anisotropy might also be relevant to cognitive distortion in SPD. In the present study, some visual memory tests, including visual reproduction and memory for faces in WMS-III and immediate and delayed recall in the Rey-Osterrieth complex figure test, demonstrated significant correlation with UF area, suggesting that the ventral visual pathway involved with UF might also be affected in SPD.

The present findings of significant reduction of anisotropy with a trend-level increase of mean diffusivity in UF could be attributed to 1) decreased density of axons; 2) decreased degree of myelination of axons; and/or 3) impaired axonal membranes. A recent postmortem study of UF in schizophrenia demonstrated that there were no differences in the number and density of fibers in UF between schizophrenic and control subjects (Highley et al 2002). Additionally, there is growing evidence suggesting that glial cells, particularly oligodendrocytes, which form myelin sheaths around axons, are abnormal in schizophrenia (Davis et al 2003; Hakak et al 2001; Uranova et al 2001a, 2001b). Hakak and coworkers, in fact, reported abnormal expression of myelin-related genes in schizophrenia, which suggests a disruption in oligodendrocyte function (Hakak et al 2001). Furthermore, Uranova and coworkers showed both qualitative and quantitative abnormalities in postmortem brains of schizophrenic subjects in the oligodendroglia of the prefrontal cortex and caudate nucleus (Uranova et al 2001a, 2001b). Also, a magnetization transfer imaging study revealed that decreased magnetization transfer ratio, a putative index of myelin or axonal density, was observed in frontal and temporal regions of schizophrenia (Foong et al 2000a, 2001). Taken together, these findings suggest that UF anisotropy reduction might be attributed to oligodendrocyte dysfunction within the fronto–temporal circuitry. Because SPDs in our study also showed disturbed UF anisotropy, it is possible that a similar process might be occurring in SPD, although future studies focused on glial cells are needed to confirm such speculations.

We note several methodological issues in our study. One limitation is that DTI is more prone to artifact, including partial volume effects, chemical shift artifacts, bulk motion, and spatial distortion, compared with standard MRI acquisition protocols used for most volumetric studies, and thus such artifacts might have influenced our findings. The resolution of DTI is also low compared with most recent volumetric studies, and low spatial resolution can increase partial volume effects, which could decrease mean anisotropy, particularly within small ROIs; however, the LSDI (Gudbjartsson et al 1996; Maier et al 1998) protocol we used is less prone to chemical shift artifacts, bulk motion, and spatial distortions than is the conventional single-shot diffusion-weighted echo-planar protocol (Turner et al 1990), although the LSDI sequence is four to six times slower (Kubicki et al 2004). Moreover, with LSDI, motion artifact can be monitored for each voxel, and we...
demonstrated that motion artifact did not differ significantly between groups. Furthermore, to reduce partial volume effects, we took advantage of coronal image acquisitions that were perpendicular to both the densest portion of the UF at the temporal stem and the largest portion of the CB. We are thus confident that, given the current state-of-the-art technology, we controlled for the influence of possible artifacts due to the method we used.

Also of note, our group developed a directional threshold method for cross-sectional ROI definition of fiber bundles, such as UF and CB. The greatest advantage of this method is that it is based on directional information obtained only from the diffusion tensor, whereas conventional fixed ROI methods and exploratory voxel-based approaches discard this important information. There are limitations to this method, however. First, it works only for the unidirectional portion of fiber bundles and not for their dispersive portions or for fiber crossings. Therefore, we were limited to just one slice that included the densest portion at the anterior temporal stem to evaluate UF, and we excluded CB portions outside of the anterior and posterior boundaries defined by the genu and splenium of corpus callosum. Second, torque of the brains or any shape asymmetries that might exist between groups might affect the main direction of the bundle or threshold and thus might affect the anisotropy results, although all the DTI images were aligned to the AC-PC line with T1-weighted images to minimize these possibilities. Third, this method produces an additional variable, the cross-sectional area within the ROI defined by thresholding $\lambda_{xx}$ magnitude; however, this cross-sectional area has not been well interpreted physiologically, although it is speculated that it might also yield a quantitative measure of connectivity between different brain regions because it includes information about fiber directionality ($\lambda_{zz}$) as well as bundle volume. In fact, many meaningful correlations were observed between the cross-sectional areas and cognitive measures in the present study in SPDs and in our previous study in schizophrenia (Nestor et al. 2004).

In summary, the present DTI study of SPD demonstrates fronto–temporal connectivity through the UF in association with cognitive distortion, social deficit, and restricted affectivity, and intact neocortical–limbic connection through CB, with the latter in marked contrast with what has been reported in schizophrenia. Also, the present study offers biological commonality and distinction between SPD and schizophrenia in terms of neural connectivity. More specifically, neural circuitry through the UF might be affected in both clinical entities, whereas CB integrity might be preserved in SPD. This method thus has the potential of elucidating further the neuropathology that underlies altered neural connectivity in SPD.
