ABSTRACT
The electrical activity in the electroencephalogram (EEG) and the event-related potentials extracted from the EEG provide the greatest temporal resolution for examining brain function. When coupled with the high spatial resolution of structural magnetic resonance imaging (sMRI), the combined techniques provide a powerful tool for neuroscience in the examination of brain abnormalities in major psychiatric illnesses. Over the last 20 years, our work has examined brain structure and function in schizophrenia. Both EEG and MRI measures have indicated profound abnormalities in schizophrenia within the temporal lobe, particularly marked over the left hemisphere. Our studies of patients first hospitalized due to psychosis revealed the early course of the disease to be characterized by progressive impairment and cortical gray matter reduction, most intense near the time of first hospitalization. Knowledge of those locations and brain signals affected early should help understand the basic physiological defect underlying this progression, with potential implications for new therapeutic interventions.

INTRODUCTION
The electroencephalogram (EEG) was the first physiological technique used to examine brain activity in schizophrenia and has evolved into a powerful method for studying brain information processing activity. In today’s world of multi-modal imaging, the EEG is still unsurpassed in providing real-time, millisecond resolution of normal and pathological brain processing, literally at the speed of thought. In general, the EEG derives from summated dendritic inhibitory and excitatory post-synaptic activity in neurons, primarily pyramidal cells in the neocortex of the brain. It is important to emphasize that EEG does not typically reflect neuronal discharges, since they are usually too brief and too asynchronous. (As an aside, we note Blood Oxygenation Level Dependent (BOLD) fMRI “activation” also mainly reflects post synaptic potential (PSP) activity, which is metabolically most demanding and necessitates the increased blood flow; action potential activity is metabolically much less demanding.)

The EEG primarily reflects the activity generated in the large dendritic trees of pyramidal cells, with an especially strong representation of activity in dendrites oriented in parallel with one another and perpendicular to the plane of the scalp surface. One of the main limitations of the EEG technique is difficulty in determining the source of the recorded activity, since generators in different brain locations can produce the same EEG pattern recorded distally at the scalp.

This temporal sensitivity and spatial insensitivity of the EEG is nicely complemented by the exquisitely detailed spatial information from the structural MRI. Structural MRI provides detailed information on which brain regions show pathological reduction in gray matter in many diseases, including schizophrenia. To combine EEG and MRI information we determine the association of structural volumetric abnormalities in particular regions with particular evoked potentials. This resembles the classical “lesion” approach to behavior and disturbed physiology, where disease-caused lesions are associated with disturbed behavior or physiological processing. Historically, this method has been productively used by many investigators dating back to Dax, Broca and Wernicke localizing language and speech functions to the left hemisphere on the basis of postmortem lesion data.

This methodology has advantages over some other source localization methods in that the associations are not subject to the caveat that dipole source localization techniques do not have unique solutions. We illustrate this method using the P300 and the Mismatch Negativity event-related potentials (ERPs) in schizophrenia.

P300 IN FIRST EPISODE SCHIZOPHRENIASUBJECTS
Association of left temporal amplitude with gray matter volume of left superior temporal gyrus volume

Following our demonstration in chronic schizophrenia of an association between left posterior superior temporal gyrus (STG) gray matter volumes and left-sided reductions in P300 with thought disorder,1 we began to examine P300 in patients at, or within 1 year of, their first hospitalization. Like chronic patients, P300 is reduced in both schizophrenia and affective disorder at first hospitalization along the middle of the scalp, but schizophrenia patients selectively show a left temporal area P300 reduction.4 In a subset of patients, we recorded P300 and performed MRI. First-episode subjects with schizophrenia (n = 15) or affective psychosis (n = 18) and control subjects (n = 18) silently counted infrequent target tones amid standard tones (oddball
Figure 1.
Top. P300 to target tones. Note the lateralized amplitude reduction at over left temporal scalp areas in schizophrenia. Bottom. Pearson correlation r-values between posterior superior temporal gyrus (STG) and P300 in schizophrenia. The gray matter volume of the left posterior STG shows a regionally selective association with P300 amplitude, but the gray matter volume of the right posterior STG does not. (After McCarley et al. 2002).

Figure 2.
Conjoint progression of gray matter loss in Heschl’s gyrus (dark blue and green in MRI images) and reduction of Mismatch Negativity (MMN) over 1.5 years after first hospitalization in schizophrenia, but not in affective (manic) psychosis. (After Salisbury et al. 2007).
Like the original report, patient and control subjects did not differ in psychiatrically-well subjects served as controls. Samples were likely to contain MMN generators. Patients were tested 6 months or measured in particular for left and right Heschl’s gyrus, containing MRI from a subset of patients, obtained as described above and in control subjects.

Patients with schizophrenia but not in patients with affective psychosis and positively correlated (r>0.5) with left temporal P300 voltage in (14.6% and 21.1%, respectively). Left posterior STG and the left (21.0% relative to both) and a smaller total Heschl’s gyrus volume (14.6% and 21.1%, respectively). Left posterior STG and the left planum temporale, but not other regions of interest, were specifically and positively correlated (r>0.5) with left temporal P300 voltage in patients with schizophrenia but not in patients with affective psychosis or in control subjects.

Thus, both chronic and first hospitalized schizophrenia patients show reduced P300, particularly marked over the left hemisphere, that correlates with reductions in left posterior STG. These combined functional and structural measures home in on an area with important roles in language, memory, and attention, in which pathophysiology is central to the symptoms and course of schizophrenia.

MISMATCH NEGATIVITY

Initial and longitudinal association of amplitude with left Heschl’s gyrus volume and volume reduction over time

Whereas P300 indexes the active detection of “oddball” stimuli, another brainwave is elicited automatically by small to moderately different oddballs, even when the subject is not actively attending the tones. This small negativity, termed the mismatch negativity (MMN), was generated by tones presented 3/sec as subjects performed a visual distractor task. MMN amplitude was measured from the midline anterior site (Fz), where it is typically largest. Amplitude was quantified as the mean voltage from 100 to 200 msec in the subtraction waveform constructed by removing the brain activity to standard, repetitive stimuli as the mean voltage from 100 to 200 msec in the subtraction waveform.

COMMENT

These data suggest that the conjoint use of structural MRI and ERPs can provide important information on the brain gray matter sources of ERP abnormalities in schizophrenia and bipolar disorder. Of interest with respect to the sensitivity of the method, the initial test of association between MMN amplitude within the schizophrenia group showed a significant correlation with reduced volume, although MMN amplitude itself did not differ across groups. We interpret this as evidence of a beginning pathological process in Heschl’s gyrus which orders MMN within schizophrenia, and MRI reductions.

In schizophrenia, the combined use of high temporal resolution EEG methods and high spatial resolution MRI methods have indicated brain areas involved specifically in the brain disorder known as schizophrenia, and have shown a progressive course to the disease peri-onset. We speculate that the progressive changes are related to a deficiency in inhibition from projections of the parvalbumin-containing GABAergic neurons in the cortex to pyramidal neurons. This may lead to unchecked excitation in the pyramidal neurons which in turn may act on their targets to produce excitotoxic changes, leading to neuronal regression from the loss of dendrites and synapses. Supporting this
model are the neuropathological findings of loss of soma volume in deep layer 3 of the auditory primary and secondary cortex — pyramidal cell somal volume is correlated with the extent of dendritic arborization and number of dendritic spines. Of note, an impaired GABAergic-glutamatergic (pyramidal neuron) interaction may also be the basis of the observed gamma band deficiency in schizophrenia, both for steady state and evoked gamma. The field’s growing awareness of the importance of altered glutamatergic activity in schizophrenia has recently been underscored by the promising initial clinical results of a new schizophrenia drug that activates the presynaptic metabotropic glutamate 2/3 receptors and reduces glutamate release.
